Abstract. We present a language L_n which is recognizable by a probabilistic finite automaton (PFA) with probability $1 - \epsilon$ for all $\epsilon > 0$ with $O(\log^2 n)$ states, with a deterministic finite automaton (DFA) with $O(n)$ states, but a quantum finite automaton (QFA) needs at least $2^{\Omega(n/\log n)}$ states.

1 Introduction

A PFA is generalization of DFA. Many authors have tried to find out ([2], [5], [7], [4] a. o.) the size advantages of PFA over DFA. On the other side it is known ([3], [2]) that the size of reversible finite automata (RFA) and the size of QFA exceed the size of the corresponding DFA almost exponentially for some regular languages (i.e. for languages recognizable by DFA). And so A. Ambainis, A. Nayak, A. Ta-Shma, U. Vazirani [3] wrote:

Another open problem involves the blow up in size while simulating a 1-way PFA by a 1-way QFA. The only known way for doing this is by simulating the PFA by a 1-way DFA and then simulating the DFA by a QFA. Both simulating a PFA by a DFA ([7], [5], [6]) and simulating DFA by a QFA (this paper) can involve exponential or nearly exponential increase in size. This means that the straightforward simulation of a probabilistic automaton by a QFA (described above) could result in a doubly-exponential increase in size. However, we do not know of any examples where both transforming a PFA into a DFA and transforming a DFA into a QFA cause big increases of size. Better simulations of PFA by QFAs may well be possible.

We will solve this problem.

2 Definitions and known results

We use the definition of 1-way QFA (further in text simply QFA) as in [2] and [3]. This model was first introduced in [1] and is not the most general one, but is easy

to implement and deal with. A quantum finite automaton has a finite set of basis states Q , which consists of three parts: accepting states (Q_{acc}), rejecting states (Q_{rej}) and non-halting states (Q_{non}). One of the states, q_{ini} , is distinguished as the starting state.

Inputs to a QFA are words over a finite alphabet Σ . We shall also use the symbols $\emptyset$ and $\$$ that do not belong to Σ to denote the left and the right end marker, respectively. The set $\Gamma = \Sigma \cup \{\emptyset, \$\}$ denotes the working alphabet of the QFA. For each symbol $\sigma \in \Gamma$, a QFA has a corresponding unitary transformation U_σ on the space $\mathbb{C}^Q$.

At any time, the state of a QFA is a superposition of basis states in Q . The computation starts in the superposition $|q_{ini}\rangle$. Then the transformations corresponding to the left end marker $\emptyset$, the letters of the input word x and the right end marker $\$$ are applied in succession to the state of the automaton, unless a transformation results in acceptance or rejection of the input. A transformation consists of two steps:

1. First, U_σ is applied to $|\psi\rangle$, the current state of the automaton, to obtain the new state $|\psi'\rangle$.
2. Then, $|\psi'\rangle$ is measured with respect to the observable $E_{acc} \oplus E_{rej} \oplus E_{non}$, where $E_{acc} = \text{span}\{|q\rangle \mid q \in Q_{acc}\}$, $E_{rej} = \text{span}\{|q\rangle \mid q \in Q_{rej}\}$, $E_{non} = \text{span}\{|q\rangle \mid q \in Q_{non}\}$. The probability of observing E_i is equal to the squared norm of the projection of $|\psi'\rangle$ onto E_i . On measurement, the state of the automaton "collapses" to the projection onto the space observed, i.e., becomes equal to the projection, suitably normalized to a unit superposition. If we observe E_{acc} (or E_{rej}), the input is accepted (or rejected). Otherwise, the computation continues, and the next transformation, if any, is applied.

A QFA is said to *accept* (or *recognize*) a language L with probability $p > \frac{1}{2}$ if it accepts every word in L with probability at least p , and rejects every word not in L with probability at least p .

A RFA is a QFA with elements only 0 and 1 in the matrices. A PFA is the same as a QFA but only instead of unitary matrices it has stochastic ones. A DFA is a PFA with only 0 and 1 in the matrices.

The *size* of a finite automaton is defined as the number of (basis) states in it. More exact definitions one can find, for example, in [2].

In [2] there was given a language $L_n^\times$ consisting of one word a^n in a single-letter alphabet and it was proved:

- Theorem 1** 1. Any deterministic automaton that recognizes $L_n^\times$, has at least n states.
2. For any $\epsilon > 0$, there is a probabilistic automaton with $O(\log^2 n)$ states recognizing $L_n^\times$ with probability $1 - \epsilon$.

Sketch of Proof. The first part is evident. To prove the second part, Freivalds [5] used the following construction. $O(\frac{\log n}{\log \log n})$ different primes are employed and $O(\log n)$ states are used for every employed prime. At first, the automaton randomly chooses a prime p , and then the remainder modulo p of the length of

input word is found and compared with the standard. Additionally, once in every p steps a transition to a rejecting state is made with a "small" probability $\frac{const p}{n}$. The number of used primes suffices to assert that, for every input of length less than n , most of primes p give remainders different from the remainder of n modulo p . The "small" probability is chosen to have the rejection high enough for every input length N such both $N \neq n$ and ϵ -fraction of all the primes used have the same remainders mod p as n . $\square$

In [3] was definition and theorem:

Definition 2 $f : \{0, 1\}^m \times R \mapsto \mathbb{C}^{2^n}$ serially encodes m classical bits into n qubits with p success, if for any $i \in [1..n]$ and $b_{[i+1, n]} = b_{i+1} \dots b_n \in \{0, 1\}^{n-i}$, there is a measurement $\Theta_{i, b_{[i+1, n]}}$ that returns 0 or 1 and has property that $\forall b \in \{0, 1\}^m : Prob(\Theta_{i, b_{[i+1, n]}} | f(b, r)) = b_i) \geq p$.

Theorem 3 Any quantum serial encoding of m bits into n qubits with constant success probability $p > 1/2$ has $n \geq \Omega(\frac{m}{\log m})$.

And also in [3] there was defined an r -restricted 1-way QFA for a language L as a 1-way QFA that recognizes the language with probability $p > 1/2$, and which halts with non-zero probability before seeing the right end marker only after it has read r letters of the input.

The following theorem was proved:

Theorem 4 Let M be a 1-way QFA with S states recognizing a language L with probability p . Then there is an r -restricted 1-way QFA M' with $O(rS)$ states that recognizes L with probability p .

3 Results

One of the components of the proof of Theorem 5 below is the following lemma:

Lemma 1. *Language*

$$L_1 = \{\omega \in \{0, 1\}^* : \exists x, y \in \{0, 1\}^* : \omega = x00y\}$$

is recognizable by a DFA.

Sketch of Proof. The automaton has five states: q_0, q_1, q_2, q_{acc} and q_{rej} . Values of the transition function between states are: $f(q_0, 0) = q_1, f(q_0, 1) = q_0, f(q_1, 0) = q_2, f(q_1, 1) = q_0, f(q_2, 0) = q_2, f(q_2, 1) = q_2, f(q_0, \$) = q_{rej}, f(q_1, \$) = q_{rej}, f(q_2, \$) = q_{acc}$. $\square$

Theorem 5 For all $k \geq 1, n = 2^*k$, we define language

$$L_n = \{\omega \in \{0, 1\}^n : \exists x, y \in \{0, 1\}^* : \omega = x00y\}.$$

0. There is a RFA (so also a QFA, a PFA and a DFA) that recognize L_n .
1. Any RFA that recognizes L_n , has at least $2^{O(n)}$ states.

2. Any QFA that recognizes L_n with probability $p > 1/2$, has at least $2^{\Omega(\frac{n}{\log n})}$ states.
3. Any DFA that recognizes L_n , has at least $O(n)$ states.
4. For any $\epsilon > 0$, there is a PFA with $O(\log^2 n)$ states recognizing L_n with probability $1 - \epsilon$.

Proof.

Zero part follows from fact that all finite languages are recognizable by some RFA and L_n is finite language.

First part: We give to automaton word $a_1 1 a_2 1 a_3 1 a_4 1 a_5 1 a_6 1 \dots a_k 1$, where $a_i \in \{0, 1\}$. It is obvious that then automaton cannot decide what to answer till the end of word. We prove that automaton always has to branch at every a_i . Suppose contrary, there is a_i where automaton goes to the same state whether it read $a_i = 0$ or $a_i = 1$. Then forward we give the next symbols 01^{n-2i} and automaton cannot decide what to answer. So it must branch for every a_i , we can say it "remembers" this bit. But maybe it can merge ("forget") afterwards? No, because constructions

Fig. 1. From different states go to one with the same input symbol

are forbidden by reversibility, but construction

Fig. 2. From different states go to one with different input symbols

by the same reason as branching must occur (for all states $q_i, q_j, q_m, i \neq j$). Then it follows that automaton "remembers" all bits and the total number of states is at least 2^k .

Second part: We use technique introduced by [3]. Let M be any n -restricted QFA accepting L_n with probability $p > 1/2$. The following claim formalizes the

intuition that the state of M after n symbols in form $a_1a_2a_3a_4a_5a_6\dots a_k1$ have been read is an "encoding" (in case of RFA, so deterministic, we said "remember") of the $\{a_i\}$.

Claim. There is a serial encoding of k bits into $\mathbb{C}^Q$, and hence into $\lceil \log |Q| \rceil$ qubits, where Q is the set of basis states of the M.

Proof. Let Q_{acc} and Q_{rej} be the set of accepting and rejecting states respectively. Let U_σ be a unitary operator of M corresponding to the symbol $\sigma \in \{0, 1, \emptyset, \$\}$.

We define an encoding $f : \{0, 1\}^k \rightarrow \mathbb{C}^Q$ of k-bit strings into unit superpositions over the basis states of the QFA M by letting $|f(x)\rangle$ be the state of the automaton M after the input string $a_1a_2a_3a_4a_5a_6\dots a_k1$ where $a_i \in \{0, 1\}$ has been read. We assert that f is a serial encoding.

To show that indeed f is such an encoding, we exhibit a suitable measurement for the a_i th bit for every $i \in [1..k]$. Let, for $y \in \{0, 1\}^{n-2*i+1}$, $V_i(y) = U_{\$}U_1^{n-2*i}U_0U_{y_1}^{-1}U_{y_2}^{-1}\dots U_{y_{n-2*i-1}}^{-1}U_{y_{n-2*i}}^{-1}U_{y_{n-2*i+1}}^{-1}$. The i th measurement then consists of first applying the unitary transformation $V_i(1a_{i+1}1\dots 1a_k1)$ to $|f(x)\rangle$, and then measuring the resulting superposition with respect to $E_{acc} \otimes E_{rej} \otimes E_{non}$. Since for words with form $a_1a_21\dots 1a_i01^{n-2*i}$, containment in L_n is decided by the a_i , and because such words are accepted or rejected by then n-restricted QFA M with probability at least p only after the entire input has been read, the probability of observing E_{acc} if $a_i = 0$, or E_{rej} if $a_i = 1$, is at least p. Thus, f defines a serial encoding. $\square$

Then it follows from Theorem 3 that $\lceil \log |Q| \rceil = \Omega(\frac{k}{\log k})$, but since $k = \frac{n}{2}$, we have $|Q| = 2^{\Omega(\frac{n}{\log n})}$. From Theorem 4 it follows that any quantum automaton that recognize L_n also require $2^{\Omega(\frac{n}{\log n})}$ states.

Third part: Easy.

Fourth part: The PFA Q in Theorem 1 has one rejecting (q_{rej}), one accepting (q_{acc}), one initial (q_{ini}) state and many non-halting states q_i . We build PFA Q' recognizing language L_n with one rejecting (q'_{rej}), one accepting (q'_{acc}), one starting (q'_{ini}) state and several non-halting states $q'_{i,0}$, $q'_{i,1}$ and $q'_{i,2}$, where i is from set of states' indexes from automaton Q. For every transition from state q_i to state q_j with probability p for the input symbol a (we denote this by $f(q_i, a, q_j, p)$) there are 6 transitions in Q' (we denote it by f'):

1. $f'(q'_{i,0}, 1, q'_{i,0}, p)$
2. $f'(q'_{i,0}, 0, q'_{i,1}, p)$
3. $f'(q'_{i,1}, 1, q'_{i,0}, p)$
4. $f'(q'_{i,1}, 0, q'_{i,2}, p)$
5. $f'(q'_{i,2}, 1, q'_{i,2}, p)$
6. $f'(q'_{i,2}, 0, q'_{i,2}, p)$

For every transformation $f(q_{ini}, \emptyset, q_i, p)$, there is a transformation $f'(q'_{ini}, \emptyset, q'_{i,0}, p)$. For every $f(q_i, a, q_{rej}, p)$ there is $f'(q'_{i,k}, x, q'_{rej}, p)$ such that for all $k \in \{0, 1, 2\}$, $x \in \{0, 1\}$, and for every $f(q_i, \$, q_{rej}, p)$ there is $f'(q'_{i,k}, \$, q'_{rej}, p)$.

$p)$ for all $k \in \{0, 1, 2\}$, and for any $f(q_i, \$, q_{acc}, p)$ there are $f'(q'_{i,2}, \$, q'_{acc}, p)$, $f'(q'_{i,0}, \$, q'_{rej}, p)$, $f'(q'_{i,1}, \$, q'_{rej}, p)$.

Informally, we make 3 copies from states in Q and their meaning is similar than for states of automaton from Lemma 1. Automata computes parallel two things: is length of input word n and is there any adjacent zeroes in it. It is obviously that the accepted words are those whose length is n and there are two adjacent 0 in them.

□

4 Conclusion

We have shown that sometimes quantum automata must be almost doubly exponential larger than classical automaton. But there still remains open the other question. As follows from result of Ambainis and Freivalds [2], any language accepted by a QFA with high enough probability can be accepted by a RFA which is at most exponentially bigger than minimal DFA accepting the language. Thus follows that Theorem 5 is close to maximal gap between probabilistic and quantum automaton with high enough (this was precisely computed by Ambainis and Ķikusts [8] - greater than $\frac{52+4\sqrt{7}}{81} = 0.7726\dots$) probability of success. But it is not clear how it is when we allow smaller probability of correctness. Author do not now any lower or upper bound in this case.
